Abstract

Cancer progression is often paralleled by a decline in bone mass, raising risk of fracture. Concerns persist regarding anabolic interventions for skeletal protection, as these may inadvertently exacerbate neoplastic tissue expansion. Given bone's inherent mechanosensitivity, low intensity vibration (LIV), a mechanical signal that encourages osteoblastogenesis, could possibly slow cancer-associated bone loss, but this goal must be achieved without fostering disease progression. Seventy 12w female F1-SWRxSWJ-9 mice, a strain prone to developing granulosa cell tumors, were randomized into baseline control (BC: n=10), age-matched control (AC: n=30), and LIV (n=30), which received mechanical signals (90 Hz @ 0.3 g) for 15 m/day, 5day/w over the course of 1 year. Survival curves for AC (10 died) and LIV (8 died) followed similar trends (p=0.62), indicating longevity was unperturbed by LIV. At 1 year, bone volume of proximal tibiae in LIV mice was 25% greater than AC (p<0.02), while bone volume of LS vertebrae was 16% higher in LIV over AC (p=0.02). Primary lesions and peripheral metastases were apparent in both LIV and AC; however, overall tumor incidence was approximately 30% less in LIV (p=0.27) and, when disease was evident, involved fewer organ systems (p=0.09). Marrow-derived mesenchymal stem cells (MSC) were 52% lower (p<0.01) in LIV, and 31% lower (p=0.08) in mice lacking pathology, suggesting higher MSC levels in this model of cancer susceptibility may have contributed to tumor progression. These experiments indicate that LIV helps protect bone mass in mice inherently susceptible to cancer without compromising life expectancy, perhaps through mechanical control of stem cell fate. Further, these data reflect the numerous system-level benefits of exercise in general, and mechanical signals in particular, in the preservation of bone density and the suppression of cancer progression.

Introduction

Cancer progression is often complicated by rapid declines in bone density. This osteopenia is exacerbated by the catabolic pressures of radioablative or chemotherapeutic interventions, placing the individual at an elevated risk of fracture [1]. Just as exercise is considered an effective means of reducing the risk of cancer [2], sedentary individuals are at an increased risk of developing tumors at a wide range of anatomic sites [3]. Both cancer and its treatment regimens disrupt adult stem cell reservoirs residing in the bone marrow, populations essential to maintaining and regenerating injured tissues and organs, further suppressing the ability to repair damaged connective tissue [4].

Taking advantage of the skeletal system’s inherent sensitivity to mechanical stimuli [5], recent evidence indicates that low-magnitude, high-frequency mechanical signals induced via low intensity vibration (LIV) are anabolic to bone, perhaps serving as an exercise surrogate by introducing the spectral content of muscle contractibility into the skeletal system [6–11]. To some degree, the osteogenic nature of these mechanical signals is realized by biasing bone marrow-derived MSCs towards osteoblastogenesis, while suppressing the formation of adipose tissue [12,13]. Conversely, sedentary individuals, the infirm, or those subject to disuse due to injury, shift the fate of the bone marrow progenitor pool towards adipogenesis [6,7,13], undermining the pool of cells that contribute to skeletal mass and regeneration [14–16]. These preclinical and clinical data indicate that the absence of mechanical signals potentiates a “default” pathway of fat formation, while physical stimuli, such as exercise, can encourage lineage commitment to higher order connective tissues, including bone, muscle, ligament, and tendon.

The capacity of exercise in general, and LIV in particular, to be anabolic to bone suggests that mechanical signals may be a suitable means of protecting the skeletal system from the catabolic consequences of cancer and its therapies. However, considering the capacity of LIV to influence stem cell activity in the bone marrow [13,17,18], it is also reasonable to raise concern that these mechanical signals may enable the formation of a stromal framework of solid tumors [22-25], thus facilitating progression of the disease. This concern is magnified at the molecular level, where β-catenin, through its cytoplasmic association with the intracellular domain of E-cadherin, serves to partially mediate Wnt/Catenin osteoblastogenic signaling in response to mechanical signals [8], yet as an oncogene it is implicated in a wide array of human cancers [23]. Further, the MSC itself is suggested to be a key component of the tumor microenvironment, with evidence for a role in both suppressing [24], and promoting [25] tumor growth. Recent work which considered MSC harvested from human epithelial ovarian microenvironments showed, in comparison to non-pathological MSCs, that cancer-MSC were able to enhance ovarian tumorigenesis [26]. This suggests that mechanical regulation of MSC commitment could have far-reaching effects on cancer growth, both by driving MSC towards the formation of bone, and/or influencing the progression of the tumor itself.

The experiments reported herein use a mouse model genetically prone to tumorigenesis to determine if the introduction of LIV compromises longevity, protects bone density, promotes tumor formation, and/or biases the fate of bone marrow-derived progenitor populations. The uniqueness of this mouse strain resides in the development of spontaneous granulosa cell tumors (GCT) of the ovary within ~30% of the population [27,28]. Tumorigenic onset occurs at approximately 3 months of age, which then proceed to metastasize to the lungs and liver [27-29].

Materials and methods

Animal model

All experiments and procedures were reviewed and approved by the Stony Brook University Institutional Animal Care and Use Committee (IACUC). An F1 strain of 70 female, SWRxB6WyJ-9 mice (The Jackson Laboratory; Bar Harbor, ME), crossbred to create a gct1 mutation, was chosen for its genetic propensity to develop spontaneous granulosa cell tumors at around 3 months of age. Tumorigenesis occurs naturally and spontaneously in these animals, meaning that no external pressures, such as those administered through chemical induction or cell line injection, were used at the beginning time point in the study. Importantly, acquiring the disease is not a certainty in these mice. This mouse strain was selected for that very “attribute”, to establish if the mechanical signals influenced the appearance of the disease and/or provoked an early death.

Environmental conditions remained at 12 h light/dark cycles in a 20 °C facility. Animals were housed individually, fed ad libitum, and weighed weekly. Distribution of animals into Baseline Control (BC), Age-matched Control (AC), and Low Intensity Vibration (LIV) groups were determined using a Matlab program that specifically randomizes large sample sizes by weight matching.

Daily mechanical loading protocol

The daily loading regimen consisted of placing animals into individual 12 cm × 12 cm containers on a fixed, vertically-oscillating platform (modified from Marodyne Medical; Lakeland, FL) to administer the LIV signal; 90 Hz for 15 min/day for 5 days/week at 0.3 g ± 0.025 (where 1 g = Earth’s gravitational field, or 9.8 m/s²). The displacements necessary to cause such accelerations at this frequency are less than 100 μm, and are barely perceptible to human touch. AC underwent identical handling and loading protocols as LIV, but without the platform being activated. Animal age at the beginning of the experimental protocol was 3 months, with the goal of extending the experiment for 1 year (15 months of age). Other than determining survivability curves, no data from AC or LIV mice that died naturally during that one year experimental period were used in the analyses listed below.

Tissue harvesting and analysis

Mice surviving the 1 year experimental protocol were first anesthetized using isoﬂurane inhalation, at which point whole blood was collected via cardiac puncture, heparinized and aliquoted (100 μl), followed by erythrocyte lysis (1×Pharmalyse; BD Biosciences, San Jose, CA) for FACS analysis. Euthanasia was completed by cervical dislocation. Right tibiae and femora were removed from each mouse and stored in 70% ethanol (EtOH). Marrow from left tibiae and femora were preserved in Dulbecco’s modified eagle’s medium containing 2% FBS, 10 mM HEPES Buffer, and 1% penicillin-streptomycin (DMEM+®) for FACS analysis. Tissues for histological staining, including excised tumors, were ﬁxed in 10% neutral buffered formalin (NBF), replaced at 48 h with 70% EtOH. Tissue samples of interest were sectioned and processed in 10% NBF. 5 μm, parafﬁn-embedded tissue sections were stained with hematoxylin and eosin (H&E). Diagnosis of granulosa cell tumors by histologic examination was conﬁrmed by immunohistochemical staining with calretinin (Abcam; Cambridge, MA), a molecular marker that is known to be widely expressed in GCT’S. To conﬁrm sites of leukocyte recruitment, CD45 staining (BD Pharminogen; San Diego, CA), was also performed, diluted at 1:10, 1:20, and 1:50 concentrations following heat antigen retrieval in citrate buffer. All analyses were performed blind to the experimental group each animal was in.

Flow cytometry

Flow cytometric analyses employed the use of a FACSAria cytometer (BD Pharmingen; San Diego, CA). Fluorescent antibody tagging utilized speciﬁc markers (BD Pharmingen; San Diego, CA) for hematopoietic precursors, MSCs, and immunogenic tissues. Flow cytometry data reported for AC and LIV groups represented the average of all cell populations quantiﬁed separately for each animal, processed individually for a single marker. For each sample, cells were homogenized and dissociated from their respective tissues in 3 ml of DMEM+ in order to maximize cell viability before tissue processing. Subsequent washing steps consisted of the addition of DPBS and centrifugation (4 °C, 2000 rpm, 10 min). 2 × 10⁶ cells from each tissue (with the exception of blood) were quantiﬁed individually from each animal using an automated cell counter (Scepter, Millipore; Billerica, MA), ﬁxed with 1% neutral buffered formalin (NBF) in Hank’s buffered salt solution (HBSS), and stained for speciﬁc hematopoietic markers. Speciﬁc leukocytes (CD3+, CD4+ : helper T-cells; CD3+, CD8+ : cytotoxic T-cells; CD3-, CD19+: B cells; CD11c+ : dendritic cells; CD335+: natural killer cells) were quantiﬁed based on staining for distinct surface markers. Sca-1+, c-kit+, CD90.2+, CD44+ were designated as unique MSC cell surface identifiers and populations positive for all ﬁve markers were sub-gated accordingly [18,30,31]. Hematopoietic stem cells (HSC’s) were quantiﬁed using known “LSK” markers (Lineage-, Sca-1+, and c-kit+) in conjunction with side population (SPLSK) staining (Vybrant Dyecycle Violet, Invitrogen; Rockville, MD) [32,33].

Micro-computed tomography

A range of bone morphology parameters of the proximal tibial metaphysis and L5 vertebrae was quantiﬁed ex vivo using high-resolution X-ray micro-computed tomography (μCT, Scanco Medical; Wayne, PA). These included bone volume (BV), bone volume fraction
(BV/TV), trabecular number (Tb.N), thickness (Tb.Th) and spacing (Tb.Sp), and structure model index (SMI) [34].

Proximal tibia

Beginning 300 μm distal to the growth plate, 1200 μm of the metaphysis was evaluated at 12 μm resolution and 55 keV intensity settings. A threshold for each slice was set exclusively for cortical and trabecular bone using an automated script [35]. The reconstructed solid 3D images were then used to quantify bone microarchitecture.

L5 vertebrae

A 400 μm cylindrical sample of trabecular bone from the center of the vertebral body (diameter = 0.8 mm; height = 0.4 mm; composed of 40 slices at 10 μm intervals) at 10 μm resolution and 70 keV intensity settings. The reconstructed slices generated a 3D rendering used to quantify microarchitecture as a representative region of the spine. The axial skeleton was not harvested from BC, so baseline comparisons for L5 could not be made.

Statistical analysis

Significance (p ≤ 0.05) between LIV and AC groups, and between healthy and those animals with visible evidence of tumor pathology upon gross dissection, was determined using Student’s t-test. One-way ANOVA was used for μCT analysis for baseline control and Tukey’s post hoc with a significance of p ≤ 0.05. The Mann–Whitney test was used to determine the Gaussian distribution of the data. A Kaplan Meier Survival Analysis was performed to determine if there was a difference in longevity between LIV and AC. Chi-square tests were performed to determine if the LIV signal influenced the number of animals with tumors relative to AC, and if LIV influenced the number of organs with pathology relative to those in AC.

Results

Longevity

Over the course of the study, 8 animals were lost within the LIV group (27%), while 10 were lost in AC (33%), indicating similar survivability over the 1 year course of the study (Fig. 1; p = 0.62). Unless otherwise noted, data from animals that died over the course of the study were not included in the analysis.

![Survivability curve for LIV (n = 30) and AC (n = 30) mice, with the experimental protocol beginning at 3 months of age. Both AC and LIV groups followed similar declines over the course of the 1 year period (p = 0.62), indicating that exposure to the mechanical signal did not compromise life expectancy.](image)

Bone morphology

Micro-CT analyses of the proximal tibia indicated that trabecular bone volume (Tb.BV) and bone volume fraction (Tb.BV/TV) in the 64w old AC had decreased by −47% (p < 0.01) and −45% (p < 0.01), respectively, from 12w BC (Fig. 2). In contrast, Tb.BV in 64w LIV mice was +25% greater (p < 0.03) and Tb.BV/TV +24% higher (p < 0.02) than AC. In the axial skeleton, Tb.BV was +15% (p < 0.03) and TV.BV/TV was +16% higher (p < 0.02) in the L5 vertebrae of LIV mice as compared to AC (Fig. 3). Within the same region of the L5 vertebrae, the structure model index (SMI) was 40% more plate-like in LIV than AC (p < 0.01). No significant differences between AC and LIV were observed for trabecular number (Tb.N), trabecular thickness (Tb.Th), or trabecular spacing (Tb.Sp). No differences were measured in cortical bone indices.

Histology and pathology

Animals bearing mature granulosa cell tumors (GCT) were readily identifiable due to distension of the abdomen. Upon dissection, the most prominent of all lesions were the primary solid ovarian tumors. In certain instances, ovarian cysts measuring up to 8 mm3 were also noted. Histological examination of the tumors revealed sheets of cells with central necrosis, nuclear grooves, Call-Exner bodies, and numerous mitotic figures. Immunohistochemical staining confirmed that these lesions were calretinin+ and CD45−, consistent with the diagnosis of granulosa cell tumors (Fig. 4) [28,36]. Mature ovarian tumor growth extended from the pelvic cavity into the abdominal cavity. Gross examination of the excised, mature GCT typically revealed adhesion to the kidneys and occasional extension to the thoracic spine.

Upon further inspection of the abdominal cavity, those animals with visibly evident tumors were also noted to have enlarged lymph nodes (LN) along the subcutaneous lymphatic vasculature adjacent to the hind-limb musculature, the mediastinum, and in the inguinal regions. Enlarged LN’s were found in the para-aortic regions as well but not to the extent as those of the peripheral LN’s. Histological examination of the LN’s revealed only sinus histiocytosis in some nodes, but in others metastatic granulosa cell tumors with focal necrosis was observed.

Combining the overall incidence of primary tumors and metastatic lesions in the ovaries, peripheral and aortic lymph nodes, liver and lung, this pathology pervaded 54% of AC mice, while evident in 38% of LIV that survived to 15 months of age (p = 0.27). A non-significant trend was identified in those mice with pathology evident in multiple organ systems (i.e., liver, ovary, lung), which was approximately 45% lower in mice subject to the LIV signal (p = 0.09). There was no discernible, qualitative site-specific difference in sites of tumor metastasis or tissue pathology between the groups.

Flow cytometry

At the end of the protocol, the 1 year total cell counts quantified from the marrow of AC and LIV were 12.5 × 106 and 11.5 × 106 cells, respectively, while healthy mice vs. mice with pathology contained 12.3 × 106 and 11.5 × 106 cells, respectively (nsd). Based on the five positive markers, marrow populations enriched for MSCs were −52% lower (p < 0.01) in LIV mice as compared to AC (Fig. 5a, Table 1). Regardless of treatment group, comparing MSCs in mice with no visible pathology versus those containing gross pathologic tissues showed a trend of being −31% lower (Fig. 5b; p = 0.08). The lower number (−8%) of HSC-enriched populations in the bone marrow of LIV as compared to AC mice was not significantly different (p = 0.25; Table 1). Flow cytometry data was not processed at baseline and, therefore, could not be used for comparison (simultaneous processing was not possible).
Mice with pathology: LIV vs. AC

In an effort to evaluate the influence of mechanical signals on those animals with evidence of the disease, both bone and MSC parameters were compared between AC and LIV mice with visual evidence of tumor pathology. Tb.BV/TV of the tibiae and of the L5 vertebrae of LIV mice bearing pathology showed evidence of a trend towards being higher than AC mice with pathology (+17%, p=0.12; and +13%, p=0.29, respectively; Fig. 6). The population of MSC in the BM of LIV remained significantly lower than AC by −60% (p<0.04).

Fig. 2. Reconstructions of cortical and trabecular bone in the tibial metaphysis, assayed by μCT, are shown for baseline control (BC) (left: 3 months of age), age-matched control (AC) (center: 15 months), and low intensity vibration mice (LIV) (right: 15 months). While bone quantity (BV/TV) dropped relative to BC in both AC and the mechanically stimulated (LIV) mice, the loss was mitigated in LIV by daily exposure to the mechanical signals (AC and LIV are both different from BC at p<0.01, shown by *; AC different from LIV at p<0.02, shown by **).

Fig. 3. Reconstructions of trabecular bone volume, Tb.BV, as derived from μCT scans of L5. A cylinder, 0.8 mm in diameter and 0.4 mm high, was fit into the center of the vertebral body (top left; Region of Interest represented by dashed line), such that a defined volume was taken for each specimen. The 3D reconstruction of the LIV mice (top right), revealed a bone volume fraction, Tb.BV/TV, to be +16% higher than that of the age matched controls (bottom left; p<0.02). The SMI, 40% different between groups (bottom right; p<0.01), indicated the trabecular morphology of the mechanically stimulated mice to be more plate-like in structure, rather than the rod-like struts measured in the age-matched controls. Scale is 1 mm; *=p<0.02.
Discussion

Osteoporosis, a common co-morbidity of cancer [37], is often exacerbated by aggressive chemo- and radio-therapies [37–41]. Cancer-associated declines in bone strength ultimately increase the risk of fracture, while disease or treatment-based disruption of the bone marrow stem cell pool could compromise the tissue repair process [42]. While antiresorptive agents (e.g., bisphosphonates) have helped cancer patients to mitigate these losses [43–45], concerns arise regarding long-term complications, including osteonecrosis of the jaw [46] and atypical fractures of the femur [47]. Further, the skeletal benefits of using anabolic agents may not balance concerns surrounding their role as a potential promoter of neoplastic cell expansion, and thus their use is restricted [48]. In some contrast to pharmacologic strategies, physical activity is universally promoted as a means to help preserve bone density [49]. Unfortunately, the very nature of cancer and/or its treatments is such that participating in even a mild exercise regimen can be difficult [50] and, during extreme bone loss, might precipitate the very fracture it is intended to prevent.

Mechanical signals both large (resulting in > 2,000 microstrain at the bone surface) and small (< 10 microstrain) [11], several orders of magnitude below those generated by strenuous activity [51], can positively influence bone mass, even under the added duress of disuse [52]. These mechanically-mediated enhancements in bone density are achieved, at least in part, by biasing the MSC population towards formation of skeletal tissue and away from adipose accumulation, most notably by driving MSC differentiation through the Wnt/β-catenin pathway [13,17,53–55].

To consider the use of mechanical signals as osteoprotective agents while combating cancer, whether or not in concert with cancer treatments, care must be taken to ensure that tumor growth is not accelerated. To this point, β-catenin – a key mediator of mechanically induced bone remodeling – is known to have a role in tumor growth and metastasis [23,56]. The data presented here indicate that brief, daily exposure to extremely low magnitude mechanical signals helped to preserve bone density but did not compromise survivability or promote disease progression in mice with a high propensity for the spontaneous development of GCT.

GCTs are classified as ovarian stromal tumors and are considered rare in humans, occurring in one out of every 200,000 people per year, comprising just 2% of all malignancies arising from the ovary [36]. Supporting previous studies which reported the ability of LIV...
to protect bone morphology [57,58], both the trabecular bone volume and bone volume fraction indices of the tibia and vertebrae in LIV mice were significantly higher than those measured in their AC counterparts. The structure model index (SMI), an index of bone quality [34], indicated that the LIV signal protected trabecular architecture as more plate-like, than rod-like structures, a morphology considered to be stronger and more resilient to fracture [59].

These studies also indicate that the fate of certain bone marrow–derived mesenchymal lineages can be influenced by mechanical loading, with a lower fraction of MSC being measured in bone marrow of the LIV mice as compared to the AC. In parallel, a trend was observed in that MSC-enriched populations were higher in the bone marrow of those mice bearing visible pathology — whether AC or LIV — as compared to those mice lacking tumors evident upon dissection.

The emphasis of the data presented here has been on the comparison of LIV vs. AC mice and determining if the osteoregulatory potential of mechanical signals also promoted risk of the disease. Nevertheless, as anticipated, mice from each group succumbed to the disease through the 12-month protocol, and several from each group showed evidence of pathology when examined at 15 months of age. When considering only those mice with pathology, there was a trend of reduced tumor number in the LIV mice as compared to the AC, paralleled by a significantly lower level of MSC in the bone marrow. Whether the lower MSC is simply correlated to a lower tumor burden in mice with pathology, there were — 61% fewer MSC in the bone marrow of the LIV as compared to the AC mice (left; p < 0.009). The BV/TV of the tibia (middle) and L5 vertebrae (right) of LIV mice with pathology showed a trend towards being higher than age-matched controls (17%, p = 0.13 and 8%; p = 0.31, respectively). These data indicate that the mechanical signals served to suppress MSC proliferation within the bone marrow even in mice with a tumor burden, and support some benefit in preserving bone quality despite carrying the disease.

As an indication of the spread of the disease, disparate tumor foci were quantified revealing that enlarged aortic lymph nodes, primarily reflecting increased inflammation, were actually metastatic foci, contributing further to tumor pervasion in addition to the primary ovarian tumors. A role for the suppression of tumor growth by mechanical signals was further supported by a trend of reduced tumor number in the LIV mice, as compared to AC, and the lower number of LIV mice with disease that involved more than one organ system. These data taken in combination with decreased levels of MSC-enriched populations observed in LIV mice are interpreted as a possible reflection of the benefits of exercise in reducing disease pathogenesis, perhaps by driving MSC differentiation towards higher-ordered connective tissue, such as bone or muscle, thus hindering their contribution to the stromal framework of neoplastic tissue. This perspective is supported by clinical evidence that sedentary and/or obese individuals are more susceptible to cancer [60,61], indicating that the absence of mechanical signals is permissive to the formation of adipose and neoplastic tissues. Perhaps, in the absence of the regulatory signals commanded by mechanical stimuli, the ability of progenitor populations to proliferate and spread in an undirected manner remains unheed and unchallenged.

Fig. 6. When considering only those animals that had visible evidence of pathology, there were — 61% fewer MSC in the bone marrow of the LIV as compared to the AC mice (left; p < 0.004). The BV/TV of the tibia (middle) and L5 vertebrae (right) of LIV mice with pathology showed a trend towards being higher than age-matched controls (17%, p = 0.12 and 13%, p = 0.29, respectively). These data indicate that the mechanical signals served to suppress MSC proliferation within the bone marrow even in mice with a tumor burden, and suggest some benefit in preserving bone quality despite carrying the disease.
There are a number of limitations in this study, including that the model itself does not approach 100% onset of tumorigenesis for all animals within 15 months of age (i.e., 66% of AC suffered from pathology). As the goal of the study was to determine if the mechanical signals promoted appearance of the disease, this uncertainty was considered an attribute of the model, allowing us to compare not only effects on longevity, but on incidence. Importantly, this study reports only the bone loss which occurs with 15 months of aging, rather than the bone loss which may be compounded by chemical or irradiation treatment for cancer, interventions which are certain to accelerate this loss [62]. Nor was the bone lost with age compared to that which might have occurred in a WT control. Nevertheless, the LIV signal did help protect bone quantity and quality in the skeleton, relative to the untreated age-matched controls.

Given the bone morphology measures that were made, we are not able to conclude if this mechanical protection of the skeleton was realized by an increase in bone formation, a suppression of bone resorption, or a change in levels of bone turnover. As this is an ovarian cancer, however, fluctuating hormone levels, such as that of estrogen, derived from dysplasia might contribute to variances in normal trabecular bone remodeling, a point of consideration for future work in elucidating the underlying mechanism-of-action. Severe osteolysis that is observed in occult prostate and breast skeletal metastases and primary lesions of multiple myeloma, do not appear in this model.

Follow-up studies will examine the ability of mechanical signals to suppress bone loss and cancer progression in induced models of the disease, with a continued focus on the lineage selection of the mesenchymal and hematopoietic progenitors. It should also be pointed out that the lineage selection (FACS) data were only compared at the endpoint, with no comparison to baseline measures. While this would have provided a strong index of change, confidence in FACS measures is typically derived from measures made at the same sacrifice date, using the same reagents; something that was not possible given the difficulty of breeding these mice. As importantly, in vivo animal studies must be combined with in vitro protocols used to determine if, and how, hyperplasia in cancer cells can be suppressed by mechanical signals, perhaps through pathways already identified as mechanoresponsive in MSC [63].

Conclusion

In summary, using a mouse model of spontaneous granulosa cell ovarian cancer, low magnitude mechanical signals, induced non-invasively using low intensity vibration, mitigated the long-term loss of bone relative to age-matched controls. This skeletal endpoint was achieved without compromising survival. Further, the decreased tumor burden, considered in concert with significantly lower mesenchymal stem cell populations measured in the bone marrow of LIV mice, suggest both the skeletal and disease benefits of mechanical-based interventions, including exercise, may involve biasing these progenitors towards higher-order connective tissues such as bone. Considering the brief exposure and low magnitude of these mechanical signals, these preliminary data support the potential of low intensity vibration for the suppression of bone loss in cancer patients, particularly those that are infirm or are inactive, safely achieved without the use of drugs.
